ABSTRACT

We present the results of the spatial and spectral analysis of the deep (~200 ks) *Chandra* HETG observation of the changing look AGN NGC 7582. During this long *Chandra* observation, NGC 7582 was in a highly obscured state. Therefore, we also consider a short (~24 ks) *Suzaku* observation, which caught NGC 7582 in a Compton thick state. This allows us to determine the underlying continuum model and the amount of absorption [$N_{\text{H}} = (1.2 \pm 0.2) \times 10^{24} \text{ cm}^{-2}$]. A wealth of emission lines (from Mg, Si, S, and Fe) are detected in the *Chandra* data, which allows us to map the structure of the circumnuclear emitters. The high resolution spectrum reveals that the soft X-ray emission originates in a hybrid gas, which is ionized in part by the strong circumnuclear star-forming activity and in part by the central AGN. The high resolution images confirm that the emitting region is highly inhomogeneous and extends up to a few hundred pc from the nuclear source. The X-ray images are more extended in the lower energy lines (Ne and Mg) than in the higher energy lines (Si, Fe); the former are dominated by the collisionally ionized gas from the starburst and the latter by the photoionized AGN emission. This is supported by the analysis of the He-like triplets in the grating spectra. We deduce that a low density ($n_e \sim 0.3\text{--}1 \text{ cm}^{-3}$) photoionized gas is responsible for the strong forbidden components, which is likely to originate from extended AGN narrow line region gas at distances of 200–300 pc from the black hole. We also detect an absorption feature at ~6.7 keV that is consistent with the rest frame energy of the resonance absorption line from Fe XXV ($E_{\text{lab}} = 6.7 \text{ keV}$), which traces the presence of a sub-parsec scale ionized circumnuclear absorber. The emerging picture is in agreement with our new view of the circumnuclear gas in AGN, where the medium is clumpy and stratified in both density and ionization. These absorbers and emitters are located on different scales, from the sub-pc broad line region gas out to the kpc scale of the galactic absorber.

Key words. galaxies: individual: NGC 7582 – X-rays: galaxies – galaxies: active

1. Introduction

Systematic X-ray studies with *Chandra* and *XMM-Newton* have established that our classical view of the central regions of active galactic nuclei (AGN), where the absorbing medium is a homogeneous pc-scale absorber, is too simplistic (see Bianchi et al. 2012; Turner & Miller 2009, and references therein). While we still believe that the central engine is fundamentally the same in every AGN (Antonucci 1993), we now have mounting evidence for a more dynamic and complex circumnuclear gas. Among the first AGN that unveiled that complexity are the changing look AGN, which are extremely variable sources that transition from Compton thin (i.e., column density or $N_{\text{H}} < 10^{24} \text{ cm}^{-2}$), or even unobscured, to Compton thick ($N_{\text{H}} > 10^{24} \text{ cm}^{-2}$) states (Matt et al. 2003; Guainazzi et al. 2002). While for some of these AGN a dramatic dimming in the primary emission can explain the appearance as highly obscured, as the reprocessor can echo a past and more luminous emission (e.g., NGC 4051, Guainazzi et al. 1998; NGC 2992, Gilli et al. 2000), there is also clear evidence that some of these extreme variations are due to a highly inhomogeneous absorber. Variations of the covering factor or column density (N_{H}) of the X-ray absorbing gas, with the N_{H} changing from few percent up to an order of magnitude,

are a common property of obscured AGN (Risaliti et al. 2002; Markowitz et al. 2014; Torricelli-Ciamponi et al. 2014) and argue for a high degree of clumpiness of the absorbing medium. Although the majority of the absorption changes occurs on relatively long timescales (i.e., months to years), we have witnessed N_{H} variations on timescales as short as few days or even few hours; the prototype example of the class of changing look AGN is NGC 1365 (Risaliti et al. 2005, 2007, 2009; Maiolino et al. 2010). As some of these fast N_{H} changes can be regarded as eclipsing events, where our line of sight intercepts a higher density cloud, their timescales can be directly linked to the size and distance of the absorbing clouds from the central supermassive black hole (SMBH). These rapid N_{H} variations suggest that a significant fraction of this clumpy absorber must be located very close to the nuclear X-ray source and, more specifically, within the broad line region (BLR; see Risaliti et al. 2005).

Intrinsic variability of the primary emission still plays a role as it is expected that the accretion onto the SMBH should be variable and characterized by flaring and dimming episodes, as shown by the highly variable X-ray emission of genuine unobscured AGN (McHardy 1985; Green et al. 1993). The emerging picture of AGN is thus complex and the observed spectral variability cannot be solely ascribed to either intrinsic variability

or the clumpiness of one single absorber. Further insights on these multiphase and clumpy absorbers has come from deep observations of nearby AGN with the *XMM-Newton* and *Chandra* gratings. These high spectral resolution observations revealed that the X-ray emission of AGN can be extremely rich in emission and absorption lines, tracing multiple emitting and absorbing regions, all of which contribute to shaping the observed spectra (Turner & Miller 2009). In this framework changing look AGN are an extremely important class since they can place severe constraints on the location and structure of the X-ray absorbers. They are not the exception to the AGN population, but most likely they are the sources for which we have an optimal line of sight that intercepts all the innermost and clumpy absorbers.

NGC 7582 ($z = 0.005254$) is an X-ray bright ($F_{2-10 \text{ keV}} \sim 3-8 \times 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$; Bianchi et al. 2009; Piconcelli et al. 2007, hereafter B09 and P07, respectively) Seyfert 2 galaxy, which has been observed in the X-ray band several times, from the early days of X-ray astronomy with *Einstein* and *Ginga* to the most recent X-ray observatories *XMM-Newton*, *Chandra* and *Suzaku*. NGC 7582 is classed as one of the prototype changing look AGN as it has shown remarkable variability on different timescales, both in the optical (Aretxaga et al. 1999; Turner et al. 2000) and X-ray band. Evidence for a variable and complex X-ray absorber has been reported since the low spectral resolution observations performed with *ASCA* and *BeppoSAX* (Xue et al. 1998; Turner et al. 2000). Furthermore, the first broadband X-ray observation of NGC 7582 performed by *BeppoSAX* (Turner et al. 2000) unveiled the presence of at least two X-ray absorbers, where one of them is Compton thick and covering $\sim 60\%$ of the nuclear source. A second and Compton thin absorber of $N_{\text{H}} \sim \text{few} \times 10^{22}-10^{23} \text{ cm}^{-2}$, part of which can be associated with a large scale galactic absorber, is always present and fully covers the nuclear source. Subsequent observations confirmed the extreme nature of NGC 7582, where both flux and N_{H} variations occur on different timescales, from less than a month to years. On longer timescales, such as the timescales probed with the two *XMM-Newton* observations performed in 2001 and 2005 (P07), the thicker absorber increased in column density by a $\Delta N_{\text{H}} \sim 7 \times 10^{23} \text{ cm}^{-2}$ while the thinner absorber remained constant ($N_{\text{H}} \sim 4 \times 10^{22} \text{ cm}^{-2}$). On timescales as short as a day, such as the timescale probed by two observations performed with *XMM-Newton* and *Suzaku* in April 2007 (B09), the thicker absorber varies by a typical $\Delta N_{\text{H}} \sim 10^{23} \text{ cm}^{-2}$. From the elapsed time between those two observations of about 20 h, B09 inferred a distance for the variable and higher N_{H} absorber of about $\text{few} \times 10^{15} \text{ cm}$, which is consistent with the location of the BLR.

Given the rather constant Compton reflection component and the Fe $K\alpha$ emission line detected in all the observations, a larger scale Compton thick reprocessor, which can be associated with the putative obscuring torus of the Unified Model of AGN, is also present (B09). Our line of sight is not totally blocked by this material as we are able to view a second and more compact absorber that is responsible for fast N_{H} variations. The presence of both these absorbers has been recently confirmed by two NuSTAR observations that were performed two weeks apart in 2012 (Rivers et al. 2015b). Finally, a third and Compton thin ($N_{\text{H}} \sim 10^{22} \text{ cm}^{-2}$) absorber is located at a larger distance and could be identified with the dust lane visible in both the *Hubble* Space Telescope (HST) and *Chandra* X-ray images (Bianchi et al. 2007, hereafter B07). Interestingly, since the early observations with *BeppoSAX*, NGC 7582 has clearly undergone a drop in the primary X-ray emission. Indeed, even

in the Compton thin state the observed hard (2–10 keV) flux is always on the order of $3-8 \times 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$ and it has never again reached the bright state observed with *BeppoSAX* ($F_{2-10 \text{ keV}} \sim 2 \times 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$; P07; Rivers et al. 2015b).

Here we present a detailed analysis of a deep (~ 200 ks) *Chandra* observation of NGC 7582, which was performed in April 2014 with the high energy transmission gratings (HETG; Markert et al. 1994) at the focal plane. Prior to our HETG observation, *Chandra* observed NGC 7582 with the Advanced CCD Imaging Spectrometer (ACIS; Garmire et al. 2003) twice in 2000 (for a total of ~ 20 ks), which showed that the soft X-ray emission extends over $\sim 20''$ and has a highly complex morphology. By comparing the *Chandra* and *HST* images B07 concluded that the inhomogeneity seen in the X-ray images can be in part explained by the presence of the dust lane of the host galaxy and in part traces variations of the physical properties of the emitting regions, which differ in ionization and/or density. Furthermore, as seen in other Seyfert 2s (Guainazzi & Bianchi 2007), the soft X-ray emission is dominated by emission lines from highly ionized elements (from He-like and H-like O, Ne, Mg, Si, and S), with a strong contribution to the emission from a photoionized gas (P07). However, since the *XMM-Newton*-RGS detector has a limited band pass (0.35–2.5 keV) and for NGC 7582 the spectrum had insufficient signal to noise above ~ 1 keV, most of the emission lines were only detected with *XMM-Newton* and *Suzaku* CCD detectors. Therefore, the HETG observation presented here provides the first high spectral resolution data of this changing look over the 1–10 keV energy range. During this observation NGC 7582 was in a highly obscured state, which allowed us to map the emitting regions up to the Fe-K band. The paper is structured as follows. In Sect. 2 we describe the *Chandra* and *Suzaku* observations and data reduction; in Sect. 3 we present the modeling of the *Chandra* spectrum. In Sect. 4 we compare the results of the spectral analysis with the high spatial resolution images extracted for the element of interest (i.e., Ne, Mg, and Si) and derive the main properties of the multiphase emitting gas. A summary of the structure of the circumnuclear gas in NGC 7582 is presented in Sects. 4 and 5.

2. Observations and data reduction

2.1. Chandra

Chandra observed NGC 7582 twice in 2014, on April 21 and April 22, for a total of ~ 200 ks (OBSIDs: 16079 and 16080 with 173 ks and 20 ks exposure, respectively; see Table 1). The observations were made with the HETG instruments at the focal plane of the Advanced CCD Imaging Spectrometer (ACIS-S; Garmire et al. 2003). The HETG consists of two gratings assemblies, the High-Energy Grating (HEG; 0.7–10.0 keV) and the Medium-Energy Grating (MEG; 0.4–8 keV). The HETG data

were reprocessed with the *Chandra* Interactive Analysis of Observations software package (CIAO version 4.8¹; Fruscione et al. 2006) and CALDB version 4.7.2. We extracted the spectra for each arm (−1 and +1) for the first order data of each of the HETG grating (HEG and MEG) for each observation. To extend the HEG data above 8 keV we used an extraction strip narrower (with a HETG width of 20 instead of 35) than the default. We then generated for each of the arms (−1 and +1) the spectral redistribution matrices (RMF files) with the CIAO tool MKGRMF and the telescope effective area files with the CIAO script FULLGARF, which drives the CIAO tool MKGARF. We then combined the −1 and +1 orders (using response files combined with appropriate weighting); we did not subtract the background as it is negligible. Although most of the exposure was performed during the second observation (OBSID 16079), we checked that the spectra extracted from the two OBSIDs are consistent and combined them to create higher quality summed first-order HEG and MEG spectra for fitting; again we created the response files by combining them with the appropriate weighting. Prior to any spectral fitting it is clear that NGC 7582 was in a Compton thick state for the whole duration of the *Chandra* observation because there is no evidence of the primary emission emerging in the collected spectra up to 5 keV (see Fig. 2). We binned the HEG to 1024 channels and the MEG to 2048 channels, corresponding to $\Delta\lambda \sim 0.02 \text{ \AA}$, for the main spectral fits. This binning corresponds to twice the full width half maximum (FWHM) resolution of the HEG and the FWHM of the MEG detectors. A finer binning of $\Delta\lambda \sim 0.01 \text{ \AA}$ is used later for some of the line profiles. For most of the spectral fits we considered the 1.2–7 keV and 1.9–9.5 keV energy range for the MEG and HEG, respectively; in these energy bands we collected ~ 1140 and ~ 1105 counts in the MEG and HEG spectra. Throughout the paper we adopted $H_0 = 71 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_\Lambda = 0.73$, and $\Omega_m = 0.27$ (Spergel et al. 2003). All the spectral fits are performed using XSPEC (Arnaud 1996) with the C-statistic; the fit parameters are quoted in the rest frame of NGC 7582 and errors are at the 90% confidence level for one interesting parameter, unless otherwise stated. As we are using the XSPEC software package, all fit parameters are given in energy, where we adopted the conversion factor between energy and wavelength of 1 keV being equivalent to 12.3984 \AA in wavelength. In all the fits, we included Galactic absorption with a column density $N_H = 1.9 \times 10^{20}$ (Dickey & Lockman 1990).

2.2. *Suzaku*

Four *Suzaku* (Mitsuda et al. 2007) observations of NGC 7582 were performed in 2007 with an averaged exposure time of 25–30 ks. As NGC 7582 was Compton thin in the first two observations and thick in the last two (B09), we considered only two observations representative of each state; in particular, for the thick state, we considered the fourth observation, which has an observed 2–10 keV flux similar to the flux measured with *Chandra* ($F_{2-10 \text{ keV}} \sim 3 \times 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$; see Table 2).

For the *Suzaku* data reduction, we followed the standard prescription for the filtering procedures and considered only the data from the two front illuminated (FI) X-ray Imaging Spectrometer (XIS 0 and XIS 3, Koyama et al. 2007) and the hard X-ray detector (HXD-PIN; Takahashi et al. 2007). The XIS source spectra were extracted from a circular region of 2.9′ radius centered on the source, while the background spectra were extracted from two circular regions of 2.4′ radius offset from the source

Table 2. Best-fit parameters and observed fluxes for the continuum derived with the joint fit of the *Suzaku* and *Chandra* data.

$F(2-10) \text{ keV}_{\text{Chandra}}$	$10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$	$3.3^{+0.2}_{-0.7}$
$F(2-10) \text{ keV}_{\text{Suzaku}}$	$10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$	$3.1^{+0.1}_{-0.5}$

Notes. ^(a) Normalization of the scattered power-law component. ^(b) Primary power-law component normalization. ^(c) Compton reflection component normalization. ^(d) Normalization of the thermal component is defined as $10^{-14}/[4\pi(D_A^2 \times (1+z)^2)] \int n_e n_H dV$, where D_A is the angular size distance to the source (cm), n_e is the electron density (cm^{-3}), and n_H is the hydrogen density (cm^{-3}) as defined in the MEKAL model. ^(e) Normalization of the thermal component for the *Chandra* spectra obtained after fixing the photon index of the scattered component.

and the Fe 55 calibration sources, which are in two corners of the CCDs. The XIS response and ancillary response files were produced, using the latest calibration files, with the FTOOLS tasks XISRMFGEN and XISSIMARFGEN, respectively. After checking for consistency, the spectra from the two FI-CCDs were combined in a single source spectrum. The HXD-PIN data were reduced following the latest *Suzaku* data reduction guide (the ABC guide Version 4.0²), and using the rev2 data, which include all four cluster units. The HXD-PIN background was extracted from the background event file (known as the “tuned” background), which is provided by the HXD-PIN team and accounts for the instrumental non X-ray background (NXB; Kokubun et al. 2007). The source and background spectra were extracted using the same common good time interval and the source spectrum was corrected for the detector dead time. We then simulated a spectrum for the cosmic X-ray background counts adopting the form of Boldt (1987) and Gruber et al. (1999) and the response matrix for the diffuse emission; the resulting spectrum was then added to the instrumental one.

The XIS-FI source spectra were binned to 1024 channels and then to a minimum of 50 counts per bin, while the HXD-PIN spectrum was binned to have a signal-to-noise ratio of 5 in each energy bin. The net count rates for the Compton thick state are $(0.067 \pm 0.001) \text{ counts s}^{-1}$ and $(0.052 \pm 0.003) \text{ counts s}^{-1}$ for the XIS-FI (0.6–10 keV) and HXD, respectively. Data were included from 0.6–10 keV for the XIS-FI, we also excluded the data in the 1.6–1.9 keV energy range due to calibration uncertainties; for the HXD-PIN we only considered the 14–50 keV energy range.

² <http://heasarc.gsfc.nasa.gov/docs/suzaku/analysis/abc/>

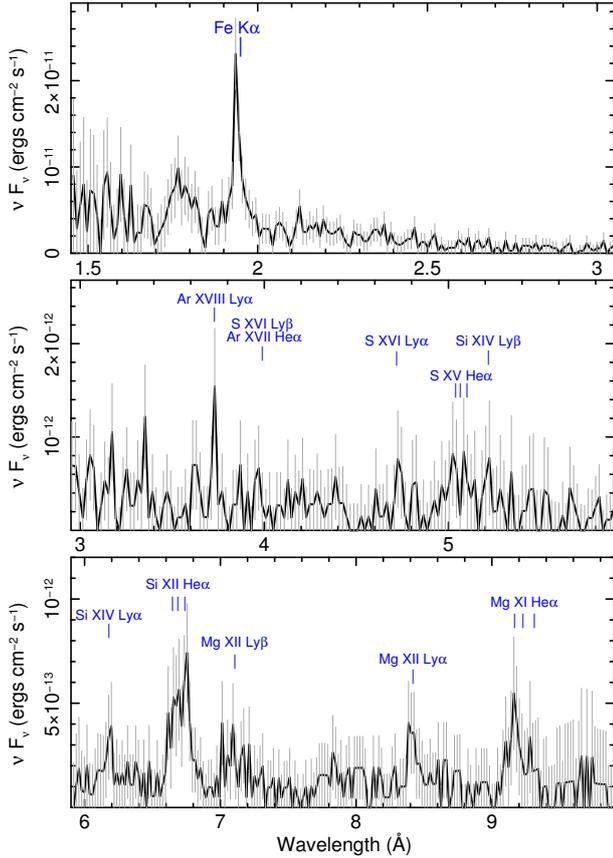

Fig. 1. *Chandra*-HETG spectrum of NGC 7582, shown vs. the rest frame wavelength (increasing in λ from the top to the lower panel). The spectra are binned at the FWHM resolution for both the HEG ($\Delta\lambda = 0.01$ Å) and the MEG ($\Delta\lambda = 0.02$ Å). The spectra have been folded against a power-law model with $\Gamma = 2$. The top panel shows the HEG spectrum in the 1.45–3 Å range (corresponding to ~ 4 –8.5 keV) covering the Fe $K\alpha$ emission line. The middle and lower panels are from the MEG grating. The strongest emission features (labeled in blue) are due to argon (at ~ 3.7 Å), sulphur (at ~ 5 Å range), silicon, with the prominent He-like triplet at ~ 6.6 Å, and magnesium (in the ~ 7 –9 Å range). The broadband spectrum is line dominated with an extremely weak continuum emission, which emerges only below ~ 2.5 Å (i.e., at $E \geq 5$ keV).

3. Spectral analysis

3.1. Continuum modeling

The first inspection of the *Chandra* data shows a spectrum dominated by emission lines with an extremely low continuum, suggesting that NGC 7582 was in a Compton thick state for the duration of the observation. In Fig. 1 we show the observed HETG spectrum in νF_ν flux units unfolded against a power-law model with a photon index $\Gamma = 2$. The spectrum is shown at the FWHM resolution of the HETG ($\Delta\lambda = 0.01$ Å and $\Delta\lambda = 0.02$ Å for the HEG and MEG, respectively) and covers the wavelength range from 1.45–10 Å (corresponding to 1.25–8.5 keV). The spectrum is plotted in wavelength to show not only the overall spectral shape but also the several emission lines that are present. Before proceeding to parameterize the emission lines, we focused on the shape of the underlying continuum. As at this point we are not interested in the finer details of the emission line profiles, we considered the HEG and MEG spectra grouped with a minimum of 10 counts per bin and fitted in the 0.7–7 keV and

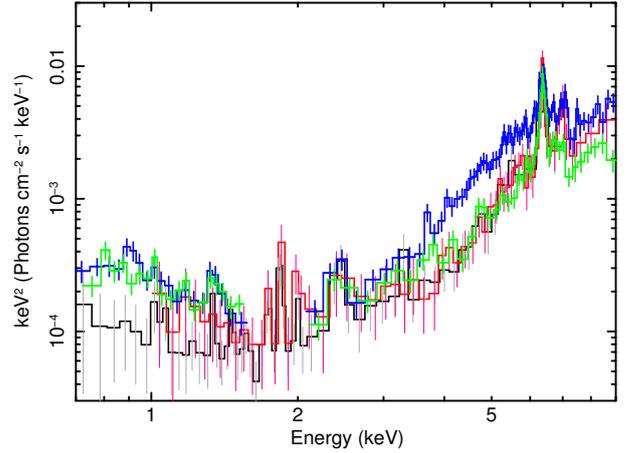

Fig. 2. Comparison between the *Chandra* (HEG and MEG; red and black data points, respectively) and two of the *Suzaku* observations, which caught this AGN in the two different states representative of the Compton thin ($N_{\text{H}} \sim 4 \times 10^{23}$ cm $^{-2}$; blue data points) and thick ($N_{\text{H}} \sim 1.2 \times 10^{24}$ cm $^{-2}$; green data points) states. Above 2 keV the *Chandra* spectra are similar in observed flux and spectral shape to the typical Compton thick state observed by *Suzaku*. In the soft X-ray band the lower flux is due to the smaller extraction region of the *Chandra* grating data. The spectra are unfolded against a power law with $\Gamma = 2$ and rebinned for plotting purposes.

1.9–9.5 keV energy range for the MEG³ and the HEG, respectively. We considered a simple baseline continuum model that is typical of a highly obscured AGN. This model is composed of an absorbed power-law component, a scattered soft power-law, and a Compton reflected continuum component (modeled with PEXRAV, Magdziarz & Zdziarski 1995), where we assumed an inclination angle of 45° , a reflection fraction of $R = 1$, and allowed its normalization to vary with respect to the primary power law. We assumed that the scattered and primary power-law component have the same photon index (Γ). This baseline continuum model provides a reasonable description of the overall spectral shape; the fit statistics is poor ($C = 463.2$ for 171 d.o.f.) and even at this coarse binning several line-like residuals are clearly present. Owing to the limited photon statistics and the lack of coverage above 10 keV, as we are not including the *Suzaku* data, both the intrinsic photon index and the amount of absorption are unconstrained. However, we can still derive a lower limit on the amount of absorption of $N_{\text{H}} > 1.2 \times 10^{24}$ cm $^{-2}$, assuming a photon index $\Gamma = 1.8$, in agreement with a Compton thick scenario.

A soft excess that is possibly associated with a starburst emission is present below 1 keV; however, while the addition of a thermal emission component (MEKAL; Mewe et al. 1985) improves the fit ($C = 407$ for 169 d.o.f.), several residuals are present as most of the line-like features that are visible in Fig. 1 are not accounted for by this model. The temperature of this component is $kT = 0.78^{+0.06}_{-0.16}$ keV and mainly improves the fit below 1 keV, but cannot account for both the strong Mg XI and Si XIII emission lines. We tested for the presence of an additional and higher temperature thermal emission component, but also in this case while the fit statistically improves ($\Delta C = 25$ for 2 d.o.f.) it still leaves strong residuals above 1.2 keV. As we show later there is evidence in the zeroth order images for some extended emission, which extends on scales of few hundreds pc from the nuclear source. This could be, in principle, associated with the narrow emission line region (NLR) gas or a hot gas connected

³ We note that adopting the additional grouping of 10 counts allows us to consider the MEG data down to 0.7 keV.

with a strong circumnuclear star formation activity. Most of the emission lines with the exception of Mg XI also show a strong forbidden component, which is indicative of a photoionized gas or at least an hybrid plasma. Therefore the simple addition of a thermal emission model cannot adequately describe the soft X-ray spectrum. This is in agreement with the analysis of the XMM-RGS data presented by P07, where, despite the larger aperture of the RGS data with respect to the *Chandra* gratings, it was already found that the soft X-ray emission in NGC 7582 has a strong contribution from a photoionized gas.

In order to better parametrize the continuum, we then repeated the fit including both the *Chandra* and *Suzaku* spectra collected during the fourth of the *Suzaku* observations (both the XIS-FI and the HXD-PIN data), which caught NGC 7582 in a Compton thick state and with a similar 2–10 keV flux. As we are not interested in the detailed modeling of the absorber, we fitted the same simple model for a Compton thick absorber/reflector and we included several Gaussian lines to account for the soft X-ray emission lines and the Fe K α emission line. Since the large point spread function (PSF) of *Suzaku* includes all the galaxy, we added a thermal emission component for the *Suzaku* data allowing for different normalizations between the *Chandra* and *Suzaku* spectra. Indeed a clear excess in the soft X-ray emission is apparent in the *Suzaku* XIS below 1 keV with respect to the *Chandra* data (Fig. 2). However, as the *Chandra* spectra have a low S/N below 1 keV, the normalization of the thermal component of the *Chandra* spectra is highly degenerate with the photon index and normalization of the scattered power-law component, so we initially fixed it to zero. This model can be expressed with the mathematical form,

$$F(E) = \text{abs}_{\text{Gal}} \times (\text{pow1} + \text{zphabs} \times \text{pow2} + \text{PEXRAV} + \text{Gaus}_{\text{soft}} + \text{Fe K}\alpha + \text{MEKAL}), \quad (1)$$

where as before we assumed the same Γ for both the scattered (pow1) and primary power-law component (pow2). Thanks to the joint fit with the *Suzaku* data, we now have some basic constraints on the primary continuum: the photon index is found to be $\Gamma = 1.74 \pm 0.18$; the column density of the absorber is, as expected, in the Compton thick regime with $N_{\text{H}} = 1.2 \pm 0.2 \times 10^{24} \text{ cm}^{-2}$; and the normalizations of the primary and reflected power-law components are $N_{\text{PL}} = 3.1_{-1.2}^{+2.4} \times 10^{-3} \text{ photons cm}^{-2} \text{ s}^{-1}$ and $N_{\text{PEXRAV}} = 1.9_{-0.9}^{+1.2} \times 10^{-3} \text{ photons cm}^{-2} \text{ s}^{-1}$ (see Table 2), which correspond to a reasonable reflection fraction of about $R \sim 0.6$. These parameters are in agreement with the best-fit model of the Compton thick state as found by B07. Although statistically the fit is still not good ($C/\text{d.o.f} = 402.1/238$), most of the remaining residuals are mainly due to additional soft X-ray emission lines in the *Chandra* spectra. The observed *Chandra* soft (0.5–2 keV) and hard (2–10 keV) X-ray fluxes are $F_{(0.5-2) \text{ keV}} \sim 1.9 \times 10^{-13} \text{ erg cm}^{-2} \text{ s}^{-1}$ and $F_{(2-10) \text{ keV}} \sim 3.3 \times 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$, respectively (see Table 2). We note that the hard X-ray flux measured with this observation is similar to all the recent observations that caught NGC 7582 in a thick state (B09; P07; Rivers et al. 2015b).

NGC 7582 was also observed with NuSTAR in 2012 on August 31 for ~ 16 ks and September 14 for ~ 14 ks (Rivers et al. 2015b). We inspected both these observations and found that while in the first observation NGC 7582 was caught in the standard Compton thin state ($N_{\text{H}} \sim 2 \times 10^{23} \text{ cm}^{-2}$), in the second NGC 7582 was in a more obscured state ($N_{\text{H}} \sim 6 \times 10^{23} \text{ cm}^{-2}$). We attempted a simultaneous fit with the *Chandra* and NuSTAR spectra as performed with the *Suzaku* data; however, while in

the 2–10 keV energy range the *Suzaku* spectra perfectly overlay on the *Chandra* data (as seen in Fig. 1), the NuSTAR spectra show a slightly different spectral shape. This could be explained with either a different N_{H} and/or an apparent harder photon index. Therefore we proceeded to adopt the best-fit continuum described by the joint analysis of the *Chandra* and *Suzaku* spectra in the Compton thick state (see Table 2).

3.2. Emission line component

After having reached a good representation of the underlying continuum, we then proceeded to build the *Chandra* emission line component model. We therefore fixed the photon index and N_{H} to the best-fit value found with the joint fit with the *Suzaku* spectra (see Table 2) and allowed the normalizations of the power-law components and reflection component to adjust upon adding the Gaussian emission lines. We considered at first the MEG and HEG data binned at $\Delta\lambda = 20 \text{ m}\text{\AA}$ (2048 and 1024 channels for the MEG and HEG, respectively) and the 1.2–7 keV and 1.9–9.5 keV energy range for the MEG and the HEG spectra, respectively. We then added several Gaussian emission lines; each individual line was considered to be statistically significant if the addition yielded an improvement of the fit statistic of $C > 9.2$ (corresponding to 99% significance for 2 interesting parameters) with the exception of possible weaker emission lines that are part of a triplet (see below). We then allowed their widths to be free; if the width was found to be consistent with being unresolved at the 90% confidence level, we then fixed it to $\sigma = 1 \text{ eV}$. Below 6 keV we detected 10 statistically significant Gaussian emission lines whose main parameters, together with the most likely identification, the improvement of the fit, and laboratory energy, are listed in Table 3. The parameters of four less significant lines are also listed as they correspond to the expected transitions from Mg XI, Mg XII, and S XVI. After the inclusion of these Gaussian emission lines, any addition of a thermal emission component did not improve the fit. This is because we considered the data only above 1.2 keV and once we accounted for the emission lines no spectral curvature (i.e., from an additional weak thermal emission component) is left unmodeled. This does not imply that we can rule out the presence of a thermal emission component, indeed as we show later, some of the emission lines could be explained with a collisionally ionized plasma.

In Fig. 3 we show a zoom into the range of interest of the strongest emission lines, noting that no other clear residuals are left; furthermore the plots show that the baseline continuum, derived from the joint fit with the *Suzaku* spectra, is a good representation of the continuum in the HETG spectra. In particular, as can be seen in the lower panel (at the Fe-K region), no further residuals due to a reflection edge are present. We then examined, when possible, each of the strongest emission lines complexes with the spectra binned at half width at half maximum (HWHM corresponding to 4096 channels for the MEG) to investigate the actual broadening of some of the emission lines that appear to be resolved and to derive a more general scenario for the emitting regions. All the emission lines appear to be detected at the expected rest frame energy; to quantify any possible inflow or outflow velocity of the emitting gas we considered the 90% errors on the energy centroids of the strongest H-like emission lines (see Tables 3 and 4). We found that although the energy centroids may suggest outflow velocities of $\sim 200\text{--}800 \text{ km s}^{-1}$, once we consider the large errors ($\pm 1000 \text{ km s}^{-1}$) they are all consistent with the systemic velocity of NGC 7582.

Table 3. Emission lines derived from the fit to the 2048 channel MEG and 1024 channel HEG spectra.

Rest energy ^a (eV)	Intensity (10 ⁻⁶ ph cm ⁻² s ⁻¹)	σ (eV)	ID ^b	Atomic energy ^c (eV)	ΔC^d /d.o.f.
1336 ⁺³ ₋₄	0.36 ^{+0.48} _{-0.32}	1 ^f	Mg XI (f)	1331	3.9/2

Notes. The statistic for the model with no lines is $C/\text{d.o.f.} = 1122.9/683$. In the last column we list the improvement of the fit upon adding each of the emission lines. ^(a) Measured line energy in the NGC 7582 rest frame. ^(b) Possible identification. ^(c) Known atomic energy of the most likely identification of the line in eV, from NIST (<http://physics.nist.gov/PhysRefData/ASD/>). ^(d) Improvement in C -statistic upon adding the line. ^(f) Denotes the parameter is fixed. ^(t) Indicates that the σ is tied to the width of another transition from the same ion species.

3.2.1. Mg XI and Mg XII emission lines

At FWHM resolution binning, in the energy range of the Mg XI triplet we clearly detected only the resonance component at $E = 1353 \pm 3$ eV; a weaker emission line may be present at the corresponding energy of the forbidden component, but it is not statistically significant ($\Delta C < 4$ for 2 d.o.f.). The resonance component is resolved with a broadening of $\sigma = 5.4^{+2.6}_{-3.5}$ eV, corresponding to a $FWHM \sim 2800 \pm 1600$ km s⁻¹; forcing it to be unresolved (i.e., 1 eV) the fit worsens by $\Delta C = 9.3$. The Mg XII Ly α line is also clearly detected ($\Delta C = 18.6$) with an $EW = 30^{+19}_{-14}$ eV and is also resolved with a $FWHM \sim 2300$ km s⁻¹ ($\Delta C = 6$ with respect to $\sigma = 1$ eV).

We then considered the MEG spectrum binned at the HWHM (i.e., 4096 channels, corresponding to a spectral resolution of $\Delta\lambda \sim 0.01$ Å) and refitted the Mg XI and Mg XII lines. The energy centroids and normalizations of the Mg XI and Mg XII emission lines are similar to the values obtained with the coarse binning, and also at this finer binning the forbidden component is not statistically required and we can only derive an upper limit on its intensity of $I < 6.5 \times 10^{-7}$ ph cm⁻² s⁻¹. Both the strong resonance component of the Mg XI and the Mg XII Ly α emission lines are resolved (see Fig. 4, upper panel and Table 4) with a possible broadening of $\sigma \sim 6$ eV, which corresponds to $FWHM$ velocity widths of 3000^{+2300}_{-1400} km s⁻¹ and 2400^{+2900}_{-1400} km s⁻¹ for the Mg XI and Mg XII lines, respectively. These line widths could suggest an origin closer in than the location of the narrow emission line region, such as from the outer BLR. However, as we

discuss in Sect. 4.1 these line widths could be an artifact due to the diffuse emission component, which broadens the lines when it is dispersed by the gratings. Indeed, as we show later in Sect. 4.1, there is evidence that the emission at these energies is spatially extended, which causes a degradation of the apparent spectral resolution. We also note that in the case of the Mg XI triplet the prominence of the resonance component with respect to the forbidden line is suggestive that the triplet is mainly produced in a collisionally ionized plasma rather than in photoionized gas (Porquet & Dubau 2000; see also Sect. 4.1.1). This could indicate that at least part of the triplet emission is associated with the circumnuclear star-forming regions, rather than the photoionized emission associated with the AGN NLR gas.

3.2.2. Si XIII and Si XIV emission lines

Both strong forbidden and resonance components of the Si XIII triplet are detected (see Tables 3 and 4 and Fig. 3), where the forbidden component appears to be marginally stronger than the resonance line, but with large uncertainties. An emission line could be present at the energy of the intercombination line (see Fig. 4, lower panel) but this is not statistically required ($\Delta C = 2$). We detected both the H-like Si XIV Ly α and Ly β (see Fig. 3 panels B and C) emission lines ($\Delta C = 23.5$ and $\Delta C = 9.4$, respectively). As for the Mg XI triplet, we then fitted the spectra at a finer binning, corresponding to a spectral resolution of $\Delta\lambda \sim 0.01$ Å for both the MEG and HEG spectra. Both the forbidden

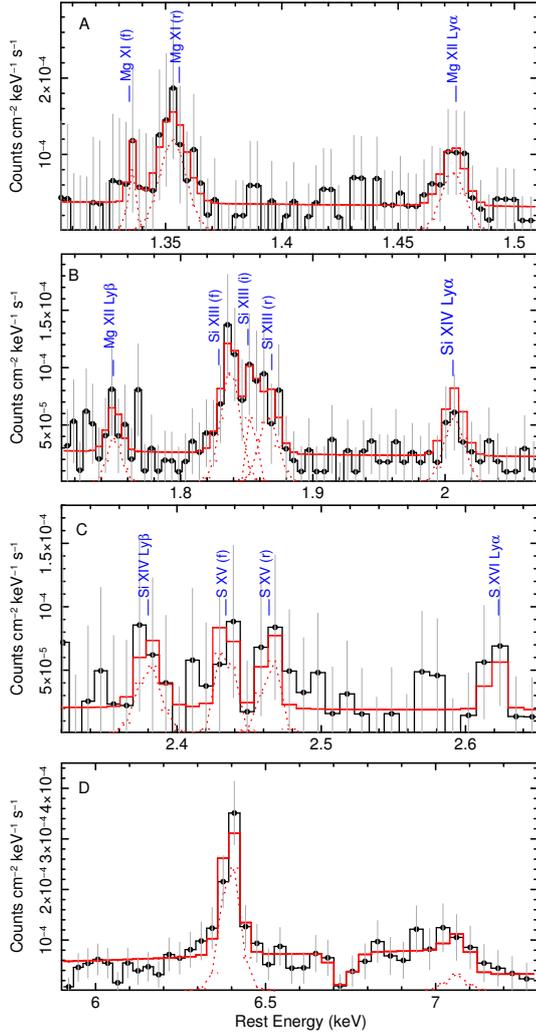

Fig. 3. Zoom into the MEG (panels A, B, and C) and HEG spectra (panel D) showing the strongest emission line features. The spectra are binned at the *FWHM* resolution for both the MEG and HEG. The main Gaussian emission lines are labeled and shown with a red dashed line. Panel A) shows the Mg XI and Mg XII Ly α region. In panel B) we show a zoom into the region of the Mg XII Ly β , Si XIII triplet, and Si XIV Ly α , Ly β emission lines, while panel C) shows the S XV and S XVI range. In panel D) we show the Fe K α region. Beside the Fe K α line at ~ 6.4 keV, a possible weak absorption feature is present at ~ 6.7 keV.

and resonance components of the He-like triplet are resolved and tying the widths of these lines to a common value results in an overall line width of $\sigma = 7^{+3}_{-2}$ eV; the improvement of the fit with respect to two unresolved emission lines is $\Delta C = 11$. A similar broadening is also required for the Si XIV Ly α and Ly β emission lines ($\sigma = 5^{+5}_{-2}$ eV). These line widths would correspond to a velocity broadening of *FWHM* ~ 2500 km s $^{-1}$ and *FWHM* ~ 1800 km s $^{-1}$ for the Si XIII and Si XIV lines, respectively. However, as we discuss later, similar to the Mg triplet, the line widths could be in part explained by the presence of a spatially extended component.

3.2.3. Sulphur and argon emission lines

Although weak we detected both the forbidden and resonance components of the S XV triplet and the Ar XVIII Ly α emission line. The S XVI Ly α emission line is marginally detected ($\Delta C = 5.4$) together with the possible Ly β emission line ($\Delta C = 7.1$);

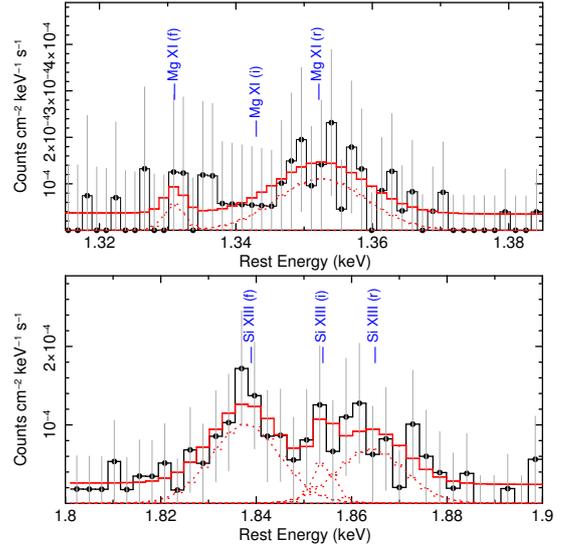

Fig. 4. Zoom into the MEG spectrum at the energy of the Mg XI and Si XIII triplets with the 4096 channels binning (i.e., at *HWHM* of the spectral resolution). The blue labels indicate the expected position of the forbidden, intercombination, and resonance transitions. The *top panel* shows the Mg XI region. While there is no evidence of emission at the energy of the forbidden component, the finer binning confirms both the strength and broadening of the resonance emission line. The *lower panel* shows the Si XIII triplet, where the finer binning confirms both the strength and broadening of the forbidden and resonance emission lines. While it is not statistically required ($\Delta C = 2$) we also included a Gaussian emission line to account for a possible intercombination component.

for the latter, however, the identification is not secure as within the errors the energy centroid is compatible with the forbidden component of Ar XVII. However, there are no strong residuals at the corresponding energy of the Ar XVII resonance component ($\Delta C < 2$). All these emission lines are unresolved at the HETG spectral resolution ($\sigma < 2$ eV). We inspected the HEG spectrum binned at $\Delta\lambda \sim 0.01$ Å to better characterize the profile of the strongest lines. We found that at this finer binning only loose constraints can be derived for the widths of these emission lines, which are all consistent with being unresolved with upper limits on the *FWHM* of ~ 3100 km s $^{-1}$.

3.2.4. Fe K α emission line

A strong Fe K α emission line is clearly detected both in the MEG and HEG spectra with a $\Delta C = 112.5$ for 3 d.o.f.; the Fe K α emission line appears to be resolved with a *FWHM* = 2500^{+1000}_{-1500} km s $^{-1}$, while the expected Fe K β is only marginally detected ($\Delta C = 4$). The measured *EW* = 290^{+80}_{-70} eV, or 1.2 ± 0.3 keV with respect to the reflection component, is in agreement with the highly obscured state of NGC 7582 (Murphy & Yaqoob 2009). As we collected ~ 600 counts in the 5–8 keV energy range and about ~ 90 counts at the energy of the Fe K α emission line, we then considered the HEG spectrum binned at the highest spectral resolution (i.e., 5 mÅ). We do not consider the MEG data as at this energy range they have a lower spectral resolution and the S/N of the spectrum is too low compared to the HEG data. The Fe K α ($E = 6.399^{+0.006}_{-0.007}$ keV) emission line is resolved with $\sigma = 17^{+12}_{-9}$ eV (see Fig. 5) and an intensity of $I = 1.8^{+0.5}_{-0.4} \times 10^{-5}$ ph cm $^{-2}$ s $^{-1}$, which is similar to the intensity

Table 4. Summary of the emission lines detected in the HETG grating data, when we considered the spectra binned at HWHM (0.01 Å for the MEG and 0.005 Å for HEG).

Line	Rest energy ^a (eV)	EW eV	σ (eV)	FWHM (km s ⁻¹)	ΔC^b
Mg XI (r)	1352 ⁺⁴ ₋₂	41 ⁺²² ₋₁₇	5.8 ^{+4.4} _{-2.8}	3000 ⁺²³⁰⁰ ₋₁₄₀₀	33.5

Fe K α^c	6401 ⁺⁶ ₋₆	267 ⁺⁷⁴ ₋₆₃	14.0 ^{+8.3} _{-7.7}	1500 ⁺⁹⁰⁰ ₋₈₀₀	101.6

Notes. ^(a) Measured line energy in the NGC 7582 rest frame. ^(b) Improvement in C -statistic upon adding the line. ^(c) The parameters of the Fe K α emission lines refers to the best-fit model after the inclusion of the possible Compton shoulder and the EW is against the total observed continuum. ^(f) Denotes the parameter is fixed. ^(t) Indicates that the σ is tied to the width of another transition from the same ion specie.

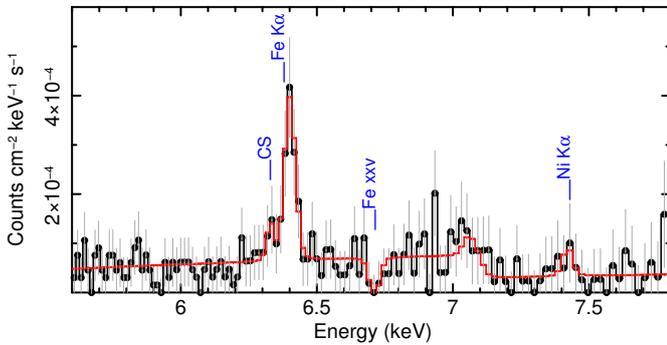

Fig. 5. HEG spectrum binned at 5 mÅ at the energy of the Fe K α emission line. The blue labels indicate the main features present in the spectrum. Although it is not statistically required we also included a Gaussian line to account for the Fe K β emission line at 7.06 keV. No clear residuals in emission are present at the expected energy of the Fe XXV and Fe XXVI lines (i.e., at 6.7 keV and 6.97 keV, respectively), which are commonly seen in highly obscured AGN. A clear absorption feature is detected at ~ 6.7 keV, which suggests the presence of a ionized absorber.

measured with all the CCD observations (see P07, B09, and Rivers et al. 2015).

We then tested whether the line width could be in part explained with the presence of the Compton shoulder, which may be expected when the line emission originates from scattering off Compton thick material (Matt 2002; Yaqoob & Murphy 2011). The inclusion of a Compton shoulder only marginally improves the fit ($\Delta C = 5$) and reduces the Fe K α line width to $\sigma = 14 \pm 8$ eV (or $FWHM = 1500 \pm 900$ km s⁻¹). Although loosely

constrained, both the centroid energy ($E = 6.32 \pm 0.18$ keV) and intensity ($\sim 15\%$ of the Fe K α intensity) of this component are in agreement with the expected values (Matt 2002; Yaqoob & Murphy 2011).

The main unexpected feature, which is detected in the HEG spectrum, is an absorption line ($\Delta C = 13.8$ for 2 d.o.f.), which is centered at $E = 6.712^{+0.004}_{-0.009}$ keV with an EW of 42^{+10}_{-15} eV. Although weak, its energy is, within the errors, consistent with the rest frame energy of the 1s–2p resonance absorption line from Fe XXV ($E_{\text{lab}} = 6.7$ keV), thus a possible origin of the line may be from a highly ionized absorber. We then explored its properties by replacing the Gaussian absorption line with a fully covering ionized absorber modeled with an XSTAR (Kallman et al. 2004) absorption grid that covers a wide range in ionization ($\log \xi = 0\text{--}6$ erg cm s⁻¹) and N_{H} ($1 \times 10^{18}\text{--}10^{24}$ cm⁻²). As the line is narrow, we tested a grid that assumes a turbulence velocity of $\sigma = 300$ km s⁻¹ and found that the absorption line is well reproduced by an absorber with $N_{\text{H}} \sim 10^{23}$ cm⁻² and $\log \xi \sim 2.8$ erg cm s⁻¹ with no net outflow velocity ($v_{\text{out}} < 1500$ km s⁻¹). This is consistent with an absorber located at distances larger than the typical disk winds (Gofford et al. 2015; Tombesi et al. 2012; Tombesi et al. 2013; Nardini et al. 2015a; see also Sect. 4.2).

4. Discussion

The high resolution X-ray spectrum of the Compton thick state of NGC 7582 is characterized by an extremely low continuum level and is rich in emission lines up to the Fe K band, which could originate in a photoionized gas that can be identified with the NLR gas, as seen in other highly

obscured Seyferts (Sako et al. 2000; Kinkhabwala et al. 2002; Guainazzi & Bianchi 2007; Kallman et al. 2014). Commonly used diagnostics for the emitting regions, when high resolution spectra are available, are the ratio between the forbidden and resonance components of the He-like triplets (Porquet & Dubau 2000), the detection of the radiative recombination continuum (RRC) transitions, the relative strength of the higher order transitions (Kinkhabwala et al. 2002), and the broadening of the line profiles. From these diagnostics we could in principle infer a first order estimate of the density, temperature (or ionization), and location of the emitting region in NGC 7582, but this technique requires a high S/N spectrum to place stringent constraints on the line profiles and intensities. Furthermore, the interpretation of the line widths and ratios could be complicated if the emitting region is extended or the emission originates from a hybrid of a photoionized and collisionally ionized plasma. In the former case, the measured line widths could be artificially broadened as a result of the spatial extent of the emission, while the latter may result in a mixture of photoionized and collisionally ionized gas contributing to the forbidden and resonance lines of He-like triplets. A complementary and important aid, however, comes from the analysis of the high spatial resolution maps of the X-ray emission lines (such as the He- and H-like O, Ne, Mg, and Si) that can be obtained with *Chandra*. This latter technique has been exploited for several nearby AGN, for which the narrowband *Chandra* images and their comparison with the optical and infrared images collected with HST (Bianchi et al. 2006; Wang et al. 2011) made it possible to map the location of the X-ray absorbers and/or emitters on a size-scale of a few tens/hundreds of pc (e.g., NGC 4945, Marinucci et al. 2012; NGC 1365, Wang et al. 2009, NGC 3393 Maksym et al. 2016; NGC 7582, Bianchi et al. 2007). In particular these studies have shown a correlation between the spatial distribution of the [O III] λ 5007 emission and the soft X-ray maps, strengthening the hypothesis that the same photoionized gas is responsible for both the optical NLR and the soft X-ray emission lines.

As shown by B07, from the analysis of the archival (snapshot) ACIS-S imaging observations, the soft X-ray emission of NGC 7582 is extended and presents a complex morphology, which varies in different energy bands, possibly tracing a stratification in the ionization of the emitting region and the presence of a Compton thin absorber located at radial scales larger than the putative torus. By comparing the HST and soft X-ray images it was also inferred that this latter absorber is most likely associated with the dust lane of NGC 7582. Indeed the softer X-ray emission comes mostly from the regions of the galaxy that are less affected by the dust absorption. We note that B07 already showed that the soft X-ray emission is more extended than the starburst region and highly inhomogeneous (see Figs. 2 and 3 of B07) with two clear hotspots that cannot be directly associated with the location of the strongest star-forming regions. This suggested that the origin of the spatially extended soft X-ray emission cannot be solely ascribed to a collisionally ionized gas and requires a medium photoionized by the central AGN.

4.1. The origin of the soft X-ray emission line component in NGC 7582

The properties of the emission lines that we detected in the HETG spectra of NGC 7582 confirm at first order the scenario derived from the analysis of the RGS data (P07), where the detection of the strong forbidden components in the He-like triplets together with the OVIII RRC suggested a strong contribution

from a photoionized plasma. However, the presence of both the forbidden and resonance components in the He-like triplets may indicate a possible hybrid of a collisional and photoionized plasma, making any line diagnostic ratios hard to interpret (i.e., in terms of density and temperature; see Porquet & Dubau 2000). Furthermore, the spatial extent of the soft X-ray emission of NGC 7582 (see B07) complicates the physical interpretation of the soft X-ray line widths in terms of their location of origin from the black hole. Therefore we investigated the spatial distribution of the soft X-ray emission, which when coupled with the line profiles could in principle allow us to infer the nature of the emitting gas. Thanks to the longer exposure of the new observation, with respect to the previous 20 ks ACIS-S exposure and the availability of the grating data, we can now create maps at higher energies than those investigated by B07 and compare them directly to the line emission observed in the high resolution spectra.

To explore this, we selected four relatively narrowbands centered on the most prominent emission line complexes; our main aim is to investigate whether the spatial distribution of the emitting gas could explain some of the broad profiles that we see in the spectrum. For this analysis, we considered the longest (173 ks) of the current ACIS-S/HETG exposures and used the zeroth order to extract the images. We extracted four images of the central region in the following bands: 0.85–1.1 keV (Ne IX–Ne X), 1.3–1.5 keV (Mg XI–Mg XII), 1.8–2.05 keV (Si XIII–Si XIV), and 6–7 keV (Fe K α). The four adaptively smoothed maps of the central 20'' \times 20'' regions are shown in Fig. 6, where we overlay the contours to highlight the spatial distribution of the X-ray counts and mark the expected position of the nucleus as reported in NED (NASA/IPAC Extragalactic Database⁴). In all the images the X-ray emission of NGC 7582 appears to be extended over different size scales depending on the energy band. Even without extracting a radial profile, it is clear that the X-ray emission is extended beyond the *Chandra* PSF, whose on-axis half energy width (HEW) is 0.5'', as it is asymmetric in almost all the energy bands. Only the Fe-K band image is more symmetric and dominated by the central point-like source.

In Fig. 7 we show color composites of the adaptively smoothed images in different energy bands corresponding to Ne (red), Mg (green, left panel) or Si (green, right panel), and Fe (blue). These false color maps demonstrate that the Ne emission is more extended with respect to the Si (Mg) and Fe bands. Furthermore, we confirm that the peak of the emission is offset between the softer and harder images (Dong et al. 2004); while in the Fe-K band image the peak is almost centered on the nucleus, the Ne band emission is offset by \sim 1.5–2'', which corresponds to a projected distance of \sim 200 pc (for NGC 7582 1'' corresponds \sim 109 pc). As already noted by B07 most of the softer (i.e., around the Ne band) X-ray emission comes from the west side of the galaxy and its asymmetric distribution can be explained with the presence of the dust lane which is in the north east direction. Diffuse X-ray emission on the west side of the hard X-ray nucleus appears in the Mg and Si energy ranges (see Figs. 6 and 7). This is in agreement with the scenario proposed by B07, where the dust lane of NGC 7582 can obscure the X-ray emission below 1 keV, but it becomes thinner at higher energies. The wide extension (\sim 6 arcsec) of the Ne band emission (Fig. 6, upper left panel) and the offset with respect to the nucleus, and thus the center of the grating extraction region, can possibly explain the nondetection of the Ne IX and Ne X emission lines in the spectra and the low photon statistics below \sim 1 keV.

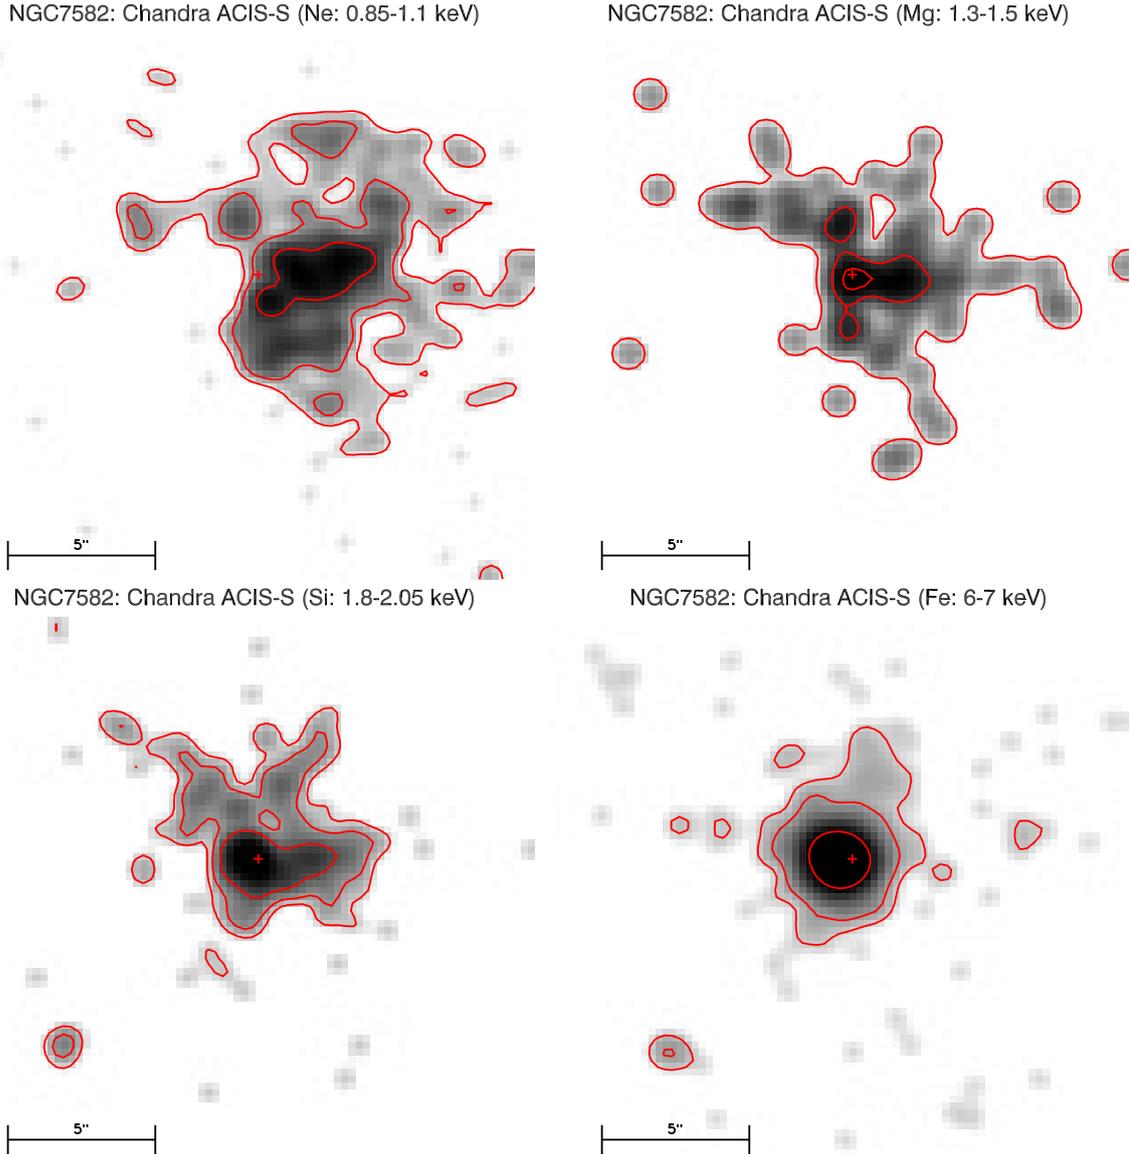

Fig. 6. ACIS-S zeroth order images of NGC 7582 mapping, *from top to bottom*, the Ne IX-X (*upper left panel*), the Mg XI-XII (*upper right panel*), the Si XIII-XIV (*lower left panel*), and the Fe K α (*lower right panel*) energy ranges. In all the images the red crosses indicate the coordinates of the nucleus (from NED) and the spatial scale is reported at the bottom (note that for NGC 7582 1'' corresponds to 109 pc). The emission appears to be spatially extended in almost all the energy ranges with a different morphology depending on the energy. The emission is progressively less extended with increasing energy and at the Fe K α emission line it is almost consistent with a point-like source, albeit with a weak elongation in the north direction. The *Chandra* PSF HEW is 0.5''.

4.1.1. Mg and Si emitter

Two main results emerged from the modeling of the Mg emission lines (Sect. 3.2.1): the lack of a significant detection of the forbidden component of the He-like triplet and a broadening of all the emission lines below 2 keV with a width of about ~ 5 eV. This latter result could explain why a thermal emission model fails to account for the soft X-ray lines because the emission lines in the MEKAL model are narrower than those observed. The lack of a forbidden emission line could be interpreted in a scenario, where the emission originates mainly in a collisionally ionized plasma, or in high density hybrid gas ($n_e > 10^{14}$ cm $^{-3}$), where the forbidden component is collisionally suppressed. However, taken at face value, a broadening of ~ 3000 km s $^{-1}$ would place this emitting gas at a distance of about ~ 0.04 pc if this broadening were interpreted as due to virial motion ($M_{\text{BH}} \sim 5.5 \times 10^7 M_{\odot}$; Wold et al. 2006);

this distance corresponds to the outer BLR, which is at odds with the extended nature of the soft X-ray emission. To reconcile these results we note that the extension seen in the Mg XI-XII map over $\sim 6''$ (see Fig. 6, upper right panel) can explain the line profiles detected in the MEG spectrum because one of the main consequences of the diffuse emission is a degradation of the spectral resolution of the grating spectra⁵. Assuming a source size of $\sim 5''$, the spectral resolution of the MEG at the energy of the Mg XI and Mg XII is degraded down to $E/\Delta E \sim 30-40$ (i.e., by a factor of 10 with respect to a point like source), which corresponds to an apparent line broadening of $\sigma \sim 15$ eV. This can easily account for the line widths observed in the Mg band. Thus the widths of the Mg XI and Mg XII emission lines (see Table 2) cannot be directly interpreted as due to a velocity broadening

⁵ See Fig. 8.23 of the *Chandra* Proposer's Observatory Guide; <http://cxc.harvard.edu/proposer/POG/>

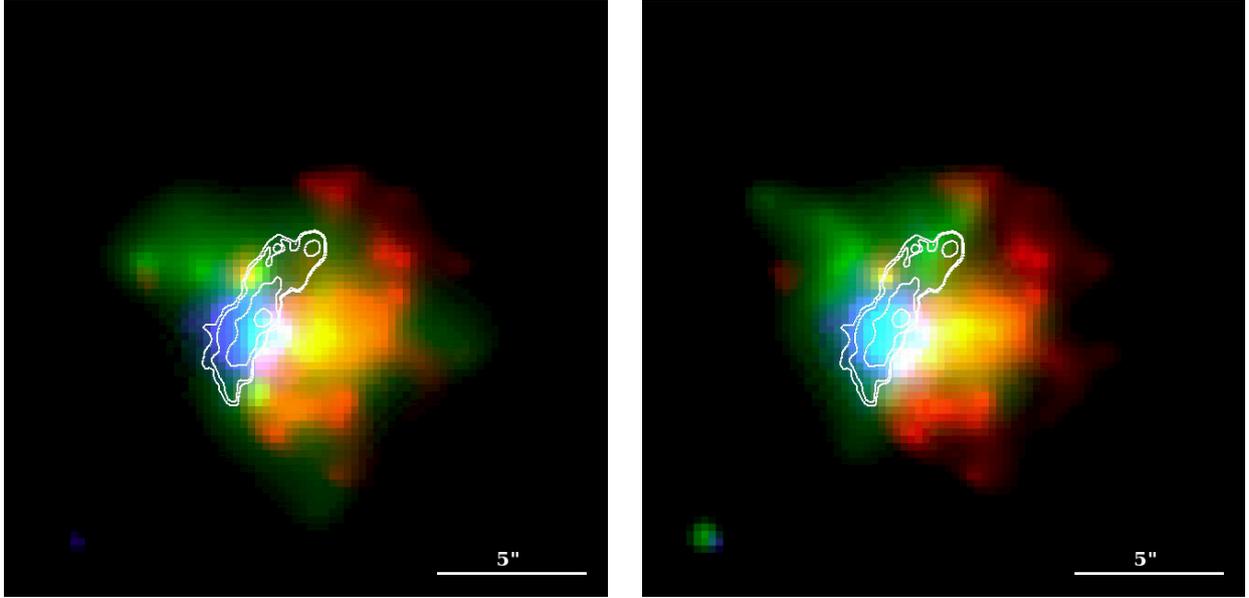

Fig. 7. False color images of the central region ($20'' \times 20''$) of NGC 7582. *Left panel:* the red represents the Ne band, green is for the Mg, and blue represents the harder emission (6–7 keV). In both of the panels the white contours show the location of the dust lane as derived from the HST images. The spatial scale is reported at the bottom (note that the *Chandra* PSF HEW is $0.5''$). The Fe K band emission is less extended and close to a point-like appearance, while both the Mg and Ne emission are clearly extended. We note that the Mg diffuse emission is more on the east side of the hard nucleus with respect to the Ne, which, although more extended, is mainly distributed on the west side. This is due to the effect of obscuration by the dust lane present in NGC 7582, which affects the lower energy band more strongly. *Right panel:* the red and blue are again the Ne and Fe bands, while the green is for the Si band. The narrower source size in the Si band with respect to the Ne and Mg emission is apparent as well as the residual excess with respect to the Fe emission.

since they are most likely an artifact of the spatial broadening. We thus conclude that a strong contribution to the Mg emission lines is from a diffuse and collisionally ionized gas, as this could explain the strong resonance line from Mg XI and the relative weakness of the forbidden component.

Our spectral deconvolution of the Si XIII and Si XIV He-like triplets revealed that the emission lines are again resolved with a similar $FWHM \sim 2000 \text{ km s}^{-1}$ and with a slightly stronger contribution from the forbidden with respect to the resonant component (see Tables 3 and 4). This suggests that we are dealing with a hybrid plasma, where the density is less than the critical value of $n_e < 10^{16} \text{ cm}^{-3}$, for which the forbidden component would be collisionally suppressed. Furthermore, even if the large uncertainties on the lines intensities do not allow us to derive more stringent constraints, the detection of the strong forbidden component suggests a contribution from a photoionized gas to the forbidden emission. The map for the Si band shows that the emission is slightly less extended (over $3''$) and more centered on the nucleus and also more symmetric than the Ne and Mg emission. However, also in this case the source size corresponds to an apparent line broadening in the MEG and HEG data similar to the measured widths.

We then attempted to quantify how much of the line emission may originate from a collisionally ionized plasma. In particular we tested whether it was possible to account for most of the Mg XI and Si XIII triplets with a collisionally ionized emission model; thus we replaced these Gaussian lines with a MEKAL component. We accounted for the measured line widths of $\sim 5 \text{ eV}$ by convolving the thermal line emission with a Gaussian broadening (via the GSMOOTH model in xspec). Although this model is statistically worse ($\Delta C = 21$ for 6 d.o.f) with respect to the Gaussian emission line best-fit model, it can formally account for the Mg XI triplet. However, for the Si XIII complex, we still need a strong contribution from a

photoionized gas; indeed we still require an additional strong forbidden line (see Fig. 8). The derived MEKAL temperature is typical of a starburst emission ($kT = 0.57^{+0.09}_{-0.07} \text{ keV}$). Its flux ($F_{0.5-2 \text{ keV}} \sim 2.7 \times 10^{-13} \text{ erg cm}^{-2} \text{ s}^{-1}$) is in agreement with the flux of the diffuse component measured in the previous *Chandra* imaging observations after the removal of the central nuclear source (LaMassa et al. 2012). The soft X-ray luminosity ($L_{0.5-2 \text{ keV}} \sim 1.7 \times 10^{40} \text{ erg s}^{-1}$) is also in agreement with the expectation from the infrared luminosity of NGC 7582 ($L_{\text{FIR}} \sim 9.6 \times 10^{43} \text{ erg s}^{-1}$; Taniguchi & Ohyama 1998) and the L_X -SFR relations derived from the X-ray observations of several starburst galaxies (Ranalli et al. 2003; Mineo et al. 2012; Pereira-Santaella et al. 2011). In particular, assuming that most of the infrared luminosity can be ascribed to the star formation activity, a $L_{\text{FIR}} \sim 9.6 \times 10^{43} \text{ erg s}^{-1}$ implies a star formation rate (SFR) of about $\sim 4 M_\odot/\text{yr}$ (Kennicutt 1998) for which the L_X -SFR relations would then predict a soft X-ray luminosity of $1-2 \times 10^{40} \text{ erg s}^{-1}$.

4.1.2. The location and density of the emitting gas

From the normalization of the thermal component ($A_{\text{MEKAL}} = 1.74^{+0.53}_{-0.47} \times 10^{-4} \text{ cm}^{-5}$), we can now derive a first order estimate of the plasma density (n_e). Indeed, by definition, the normalization of the MEKAL model is proportional to the volume emission measure ($E.M. = \int n_e n_H dV$) of the X-ray emitting gas with $A_{\text{MEKAL}} = 10^{-14} E.M. / [4\pi D_A^2 \times (1+z)^2] \text{ cm}^{-5}$, where D_A is the angular-diameter distance to the source and z is the redshift. We assumed that the gas extends for $\sim 500 \text{ pc}$ (as derived from the soft X-ray images) and derived a density of $n_e \sim 0.3 \text{ cm}^{-3}$ for a uniform spherically symmetric gas distribution. For an inhomogeneous gas with emitting clumps with a reasonable size scale of $\Delta R/R = 0.1$ (corresponding to a volumetric

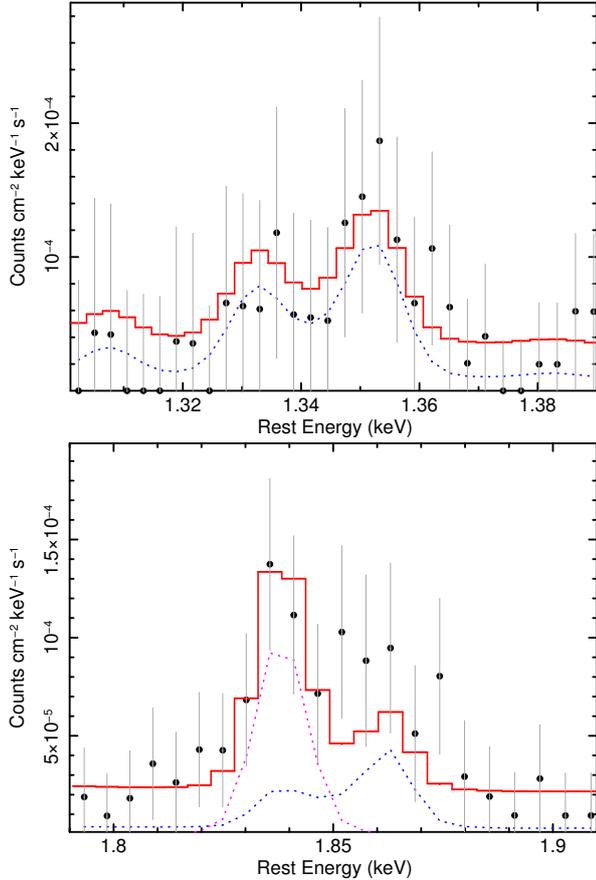

Fig. 8. Zoom into the MEG spectrum (at HWHM resolution) at the energies of the Mg XI and Si XIII triplets when modeled with the addition of a thermal emission model (blue dotted line). The *upper panel* shows the Mg XI region, where the MEKAL component can reproduce the entire profile with no need of an additional Gaussian emission line component. The *lower panel* shows that to reproduce the Si XIII triplet, we need to include a strong emission line component (magenta line) to account for the residual emission at the energy of the forbidden line. In both panels the red line shows the best-fit model where we included a MEKAL component (see Sect. 4.1.1).

filling factor of $f_v \sim 10^{-3}$), the density would be higher and of order of $n_e \sim 10 \text{ cm}^{-3}$.

In order to derive a first order estimate of the location and density of the photoionized emitter that is responsible for the soft X-ray emission lines, or at least the forbidden lines, we replaced the soft X-ray Gaussian emission lines with an XSTAR emission model and then fitted the Mg and Si emission lines. This model assumes a turbulence velocity of $v_{\text{turb}} = 1000 \text{ km s}^{-1}$ to account for the residual broadening. We only considered the MEG data because in the energy range of interest (1–2 keV) the HEG data have a lower S/N; the resulting best fits of the Mg XI and Si XIII He-like triplets are shown in Fig. 9. The ionization of this photoionized emitter is $\log \xi = 2.4^{+0.4}_{-0.3} \text{ erg cm s}^{-1}$ and its normalization is $k_{\text{xstar}} = (5.5 \pm 1.6) \times 10^{-5}$ for a column density of $N_{\text{H}} \sim 10^{21} \text{ cm}^{-2}$. The temperature of the thermal emission component is again $kT \sim 0.56 \text{ keV}$ and its soft X-ray luminosity is $L_{0.5-2 \text{ keV}} \sim 1.2 \times 10^{40} \text{ erg s}^{-1}$, which would correspond to approximately 60% of the observed soft X-ray luminosity ($\sim 2 \times 10^{40} \text{ erg s}^{-1}$). However this latter estimate must be considered as an upper limit; due to the lack of enough S/N below 1 keV, we cannot exclude the presence in the model of a lower ionization photoionized emitter, which could be responsible for the diffuse emission seen at the energy of the Ne emission lines.

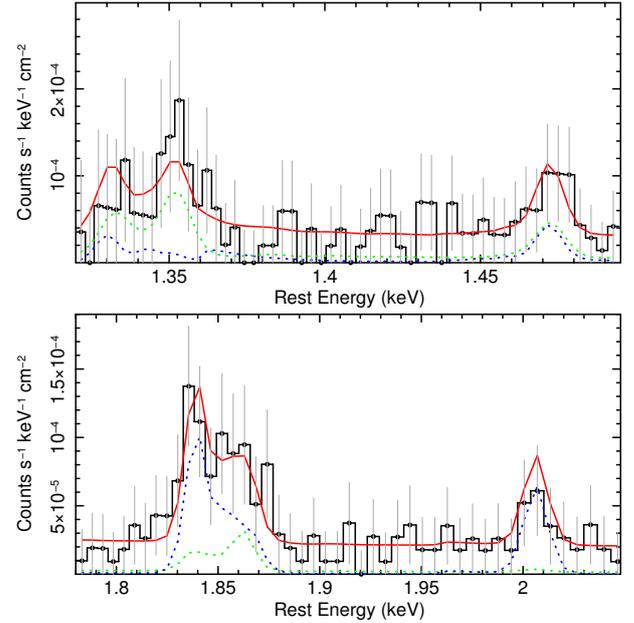

Fig. 9. Zoom into the MEG spectrum (at HWHM resolution) at the energy of the Mg XI and Si XIII triplets. The emission component is modeled with a thermal emission model (green dotted line) and a photoionized emitter, which is modeled with an XSTAR grid (blue dotted line). The *upper panel* shows the Mg XI region, where the MEKAL component can reproduce the profile with a weak contribution from the XSTAR emission component. The *lower panel* shows that the Si XIII triplet as well as the Si XIV Ly α are mainly accounted for by the photoionized emitter component (blue dotted line), while the thermal emission component accounts for the residual emission at the energy of the resonance emission line of the Si XIII triplet. In *both panels* the red line shows the best-fit model where the emission line component is accounted for by a collisional gas (MEKAL) and photoionized emitter (XSTAR; see Sect. 4.1.2).

In terms of the photoionized gas properties, a first order estimate of its density and covering factor can be derived from the XSTAR component normalization. For a shell of gas photoionized by a central source, the normalization of the emission component, k_{xstar} , is defined as $k_{\text{xstar}} = fL_{38}/D_{\text{kpc}}^2$ (Kallman et al. 2004), where L_{38} is the ionizing luminosity over the 1–1000 Rydberg range in units of $10^{38} \text{ erg s}^{-1}$, D_{kpc} is the distance to the source in kpc, and f is a geometrical factor of the emitting region with respect to a uniform shell covering a solid angle $f = \Omega/4\pi$. Since NGC 7582 was observed in a highly obscured state, before deriving the intrinsic luminosity we need to consider the Compton-down scattering effect because it can be important at this level of obscuration (Murphy & Yaqoob 2009). We thus included in the best-fit model an additional absorber (CABS model in XSPEC) with the same column density of the neutral absorber to correct for it and derived an upper limit on the intrinsic ionizing luminosity of $L_{\text{ion}} \sim 7 \times 10^{42} \text{ erg s}^{-1}$. Thus for the above ionizing luminosity and the distance of NGC 7582 ($\sim 22.7 \text{ Mpc}$), assuming a fully covering spherical shell, we derive $k_{\text{xstar}} = 1.4 \times 10^{-4}$. For a given column density, the measured normalization provides then a first order estimate of the covering factor of the emitting gas. Thus assuming a column density as above of 10^{21} cm^{-2} the ratio between the observed ($k_{\text{observed}} = (5.5 \pm 1.6) \times 10^{-5}$) and predicted normalizations gives a covering factor $f = 0.4 \pm 0.1$. We then fixed the column density to a higher value of 10^{22} cm^{-2} and derived a covering factor of only 4%, which is probably too low given the spatial extent of the soft X-ray emission. Similarly a lower limit

of $N_{\text{H}} > 2 \times 10^{20} \text{ cm}^{-2}$ on the gas density was obtained by fixing the normalization of the emitting component to the predicted value for a fully covering shell and allowing the N_{H} to vary.

An estimate of the location and density of the emitter can be then obtained using the definition of the ionization parameter $L_{\text{ion}}/\xi = nR^2$, where L_{ion} is the intrinsic ionizing luminosity over the 1–1000 Rydberg range and n is the gas density. Then assuming again a typical size of the emitting region of few hundred pc, we derived a gas density of about $n_e \sim 0.3 \text{ cm}^{-3}$. Alternatively, assuming that the gas is not highly clumped (i.e., $\Delta R/R \sim 1$) and the lower limit on the column density derived above, we can estimate a distance of $R \sim 1.4 \times 10^{20} \text{ cm}$, which is consistent with the location of the diffuse emission seen in the X-ray images and a density on order of $n_e \sim 1.4 \text{ cm}^{-3}$. Although these are an order of magnitude estimates, the similarity of the derived densities suggests that the gas is not highly clumped. Indeed, if the gas were too clumped ($\Delta R/R \sim 0.1$) the density of the single clouds would be much higher, thus to maintain the same ionization balance, as measured with the XSTAR best-fit model, the distance would be as low as few parsec, which is inconsistent with the X-ray images. Thus the most likely scenario is that the emission line component originates in a high-ionization and low-density gas ($n_e \sim 1 \text{ cm}^{-3}$), which is extended on scales of few hundreds pc. The column density of this gas is low and in the range of $2 \times 10^{20} - 10^{21} \text{ cm}^{-2}$ and has a rather high covering factor. A plausible scenario is thus that some of the soft X-ray emission lines are produced in star-forming regions embedded in a larger scale gas, which is photoionized in part by the central AGN and in part by the circumnuclear starburst itself. A similar scenario has been proposed for other highly obscured Seyfert 2, where both high spectral and spatial resolution data were available (i.e., Mrk 573, Bianchi et al. 2010; NGC 1365, Wang et al. 2009; NGC 4151, Wang et al. 2011).

4.2. Fe K band

As discussed in Sect. 3.2.4 the measured $EW \sim 1.2 \pm 0.3 \text{ keV}$ (with respect to the reflection component) of the Fe $K\alpha$ emission line is consistent with the presence of an optically thick absorber. At the energy of the Fe K band the emission map is almost consistent with a point-like source, with the exception of a weak elongation in the northern direction (see Fig. 6). We can thus treat the Fe $K\alpha$ emission line width as intrinsic to the source and attempt to place some constraints on the location of the emitter/absorber. We assumed that the broadening is due to Keplerian motion of the emitter and adopted a factor $f = \sqrt{3}/2$ to correct the observed FWHM for the geometry of the emitting gas (Netzer & Marziani 2010). Thus for a $M_{\text{BH}} \sim 5.5 \times 10^7 M_{\odot}$ (Wold et al. 2006) the measured $FWHM = 1500 \pm 900 \text{ km s}^{-1}$ would correspond to a distance of $R_{\text{FeK}\alpha} \sim 0.05 - 0.7 \text{ pc}$. The lower and upper limits on the radial distance would place the emitting gas at the distance of the outer BLR and the pc-scale torus, respectively. The derived limits for the Fe-K emitter correspond to few $\times 10^4 - 10^5 R_g$, which is in agreement with the typical location of $\sim 3 \times 10^4 R_g$, derived for a sample of nearby Seyfert 2 that had HETG observations (Shu et al. 2011).

From previous X-ray observations of NGC 7582 (P07; B09; Rivers et al. 2015b), we know that two circumnuclear absorbers co-exist in NGC 7582: one could be identified with the parsec scale torus and one is responsible for the fast N_{H} variations and is most likely located at the BLR distance. However, the measured intensity of the Fe $K\alpha$ emission line $I = (1.7 \pm 0.4) \times 10^{-5} \text{ ph cm}^{-2} \text{ s}^{-1}$ is in agreement with the historical value measured in the X-ray observations of

NGC 7582 performed over the last 10 years ($I \sim 2.2 - 2.4 \times 10^{-5} \text{ ph cm}^{-2} \text{ s}^{-1}$), which show that both the Compton reflection component and the Fe $K\alpha$ emission line do not vary. We thus conclude the Fe $K\alpha$ emission line properties are consistent with reflection from the inner edge of a Compton thick toroidal absorber (Murphy & Yaqoob 2009), which is most likely located at a subpc-, pc-scale distance from the central SMBH.

As we noted in Sect. 3.2.4 a weak absorption feature is detected at $\sim 6.71 \text{ keV}$, which could be associated with the presence of an ionized absorber. The energy centroid of this absorption is close to the expected energy of the Fe XXV resonance transition and does not require any blueshift. This suggests that the absorber is not part of a disk wind and is located further out than the typical location of few hundreds R_g of the disk winds (Gofford et al. 2015; Tombesi et al. 2012; Tombesi et al. 2013; Nardini et al. 2015a). Furthermore, the detection of this absorber when NGC 7582 is in a Compton thick state would naturally argue for a location outside the variable absorber located at the BLR distance. We can derive an estimate of the maximum distance of this absorber using the definition of the ionization parameter $L_{\text{ion}}/\xi = nR^2$, where L_{ion} is the intrinsic ionizing luminosity over the 1–1000 Rydberg range and n is the absorber density. Thus for the NGC 7582 ionizing luminosity of $L_{\text{ion}} \sim 7 \times 10^{42} \text{ erg s}^{-1}$, assuming that the absorber thickness is less than its distance (i.e. $\Delta R/R < 1$) and given the ionization parameter $\log \xi \sim 2.8 \text{ erg cm s}^{-1}$ and $N_{\text{H}} \sim 10^{23} \text{ cm}^{-2}$ we found $R \lesssim 10^{17} \text{ cm}$. This distance is on the same scale of the Fe $K\alpha$ emitting region. At this distance and again assuming a radial extent of the absorbing clouds of $\Delta R/R \sim 1$, the gas density is $n_e = 10^8 \text{ cm}^{-3}$. Although these are all first order estimates, the derived density and distance are all suggestive that this absorber is the putative electron scattering region (Krolik & Kriss 2001; Netzer 2015, and references therein), which can be associated with the inner part of the torus. On the other hand, the thick absorber could be associated with clumps within the pc-scale torus, which could vary in timescale from weeks to months.

5. Summary and conclusions

We presented the results of a detailed analysis of a deep ($\sim 200 \text{ ks}$) *Chandra* HETG observation of NGC 7582, when the AGN was in a prolonged highly obscured state with a column density in the Compton thick regime ($N_{\text{H}} \sim 1.2 \times 10^{24} \text{ cm}^{-2}$). Thanks to the combination of the high spectral and spatial resolution of the *Chandra* data, we have gained more insight in the structure of the circumnuclear emitter/absorbers of NGC 7582. As seen in other well-studied nearby Seyfert 2s and in particular for the prototype of the changing look AGN NGC 1365 (Braito et al. 2014; Nardini et al. 2015b; Rivers et al. 2015a; Risaliti 2016), it is now clear that also in NGC 7582 the absorbing and emitting circumnuclear gas is not a single homogeneous gas but it is most likely a multiphase medium, located at different distances from the sub-pc BLR region to the larger scale galactic absorber.

The main results on the different emitting and absorbing zones and their location, as obtained with this new observation of NGC 7582 can be summarized as follows:

- From the Fe $K\alpha$ emission line width and the presence in all the observations of a relatively constant reflection component, we know that a 0.05–0.7 pc scale reprocessor is present. This could be associated with the inner edge of the putative pc-scale clumpy torus. As NGC 7582 is not always absorbed by the Compton thick absorber, our line of sight

is not totally obscured by this reprocessor. Indeed, in past observations (B09) we were able to witness fast N_{H} variations due to an innermost absorber located at the BLR distance.

- A highly ionized absorber, which is responsible for the absorption feature detected at ~ 6.7 keV, is present on a similar distance to the Fe $K\alpha$ emitter and could be identified with the putative electron scattering region.
- Some of the strong soft X-ray emission lines, in particular the forbidden components, originate in photoionized emitting gas that can be associated with the extended and low density ($n_e \sim 0.3\text{--}1\text{ cm}^{-3}$) NLR gas. From the SIXT-XIV image we know that this photoionized gas is extended on size scales of 200–300 pc. Furthermore, a comparison with the Ne IX and Mg XI narrowband images shows that this gas is less extended than the emitting regions where the Ne and Mg emissions originate.
- An extended thermal gas is present on large scales (few hundreds pc) and is probably associated with the strong Ne and Mg emission. This gas is required to explain the strong resonance components and could be ionized by the circumnuclear star formation activity.
- A larger scale Compton thin absorber obscures part of the emission below 1 keV, as seen in the asymmetric map of the Ne band emission. As already suggested by B07, this absorber is presumably associated with the galactic dust lane east of the nucleus.

Although only few changing look AGN and Seyfert 2 galaxies have been observed long enough with both high spatial and spectral resolution it is now clear that changing look AGN, such as NGC 1365 and NGC 7582, have a favorable line of sight such that we can view all the stratification of these absorbers and emitters. Our results show that future deep grating observations of nearby changing look and Seyfert 2 AGN performed with *Chandra* will offer a unique opportunity to map all these emitters and absorbers. This will allow us to build a more complete picture of the AGN environment and allow us to improve the Unification Model of AGN.
